THE EFFECT OF MATERIAL COMPOSITION ON THE STABILITY OF BI-LAYERED ARCHES WITH RECTANGULAR CROSS-SECTION

1. INTRODUCTION

Curved structural and machine elements have various engineering applications [1,2,3]. Arches are commonly used in engineering structures because of their favourable load carrying capabilities. As buckling is a common way of failure, it has been the subject of investigations for quite a while. It is known that the mechanical behaviour of shallow circular arches is strongly nonlinear. In recent years, many novel mechanical models have been introduced like [3,4] by Bradford et al. These articles investigate the in-plane static behaviour of such structural elements with uniform cross-section using a one-dimensional beam model. Recent relevant results for non-uniform members were published e.g., in [5,6] by Jin et al. There are also available results for nonhomogeneous materials by Bateni et al [7,8].

In the current article, based on [9-11], it is demonstrated how the material composition affects the critical (buckling) load of bi-layered uniform shallow circular arches made of linearly elastic and isotropic materials. The mechanical model is geometrically nonlinear, using the single-layer Euler-Bernoulli beam theory. Moderately large rotations are assumed. The arch is pinned at both ends and the loading is a constant concentrated force applied at the crown point.

2. KINEMATICS

Figure 1 shows a portion of the arch; the orthogonal curvilinear coordinate system \((\xi, \eta, \zeta)\) is attached to the centroidal axis with radius \(\rho_o\) and the unit vectors are \(e_\xi, e_\eta, e_\zeta\). The cross-section of the arch is uniform and symmetric to the axis \(\zeta\). On the centroidal axis, the \(E\)-weighted first moment of the cross-section to \(\eta\) is zero. The Young modulus \(E\) can depend on \(\zeta\). The arc coordinate \(s\) is measured from the crown point while \(\varphi = s/\rho_o\) is the angle coordinate. The included angle of the arch is \(\vartheta\).

The mechanical model is based on the single-layer Euler-Bernoulli beam theory. Just as in [3,9], it considers small axial strains \(e_{oz}\) and moderately large rotations \(\psi_{oz}\) as

\[
\psi_{oz} = -\frac{dw_o}{ds} + \frac{u_o}{ds}, \quad e_{oz} = \frac{du_o}{ds} + \frac{w_o}{\rho_o}; \quad e_m = e_{oz} + \frac{1}{2} \psi_{oz}^2
\]

with \(e_m, u_o, w_o\) being the membrane strain and the pre-buckling displacements of the centroidal axis in the tangential/normal direction.

Recalling the Hooke law, the axial force \((N)\) and bending moment \((M)\) are given by [9]

\[
M = \int_A E\varepsilon_{\zeta}\zeta dA = -I_{oz}(w_o^{(2)} + w_o)/\rho_o^2, \quad N = \int_A E\varepsilon_{\zeta} dA = A_e e_m - I_{oz} e_o / \rho_o
\]

with the notations

\[
A_e = \int_A EdA; \quad I_{oz} = \int_A E\zeta^2 dA,
\]

\[
\rho_o^2 d^n(\cdots)/ds^n = d^n(\cdots)/d\varphi^n, \quad n = 1, 2, \ldots; \quad m = A_d \rho_o^2 / I_{oz}.
\]

After buckling, the increments are denoted by subscript \((\cdots)_{b}\), therefore, similarly as beforehand, the typical quantities are

\[
\psi_{omb} = u_{ob} / \rho_o - dw_{ob} / ds; \quad e_{ozb} = \frac{du_{ob}}{ds} + \frac{w_{ob}}{\rho_o}; \quad e_{mb} = e_{ozb} + \psi_{ozb} \psi_{omb}
\]
3. EQUILIBRIUM EQUATIONS

Altogether, three equilibrium states are distinguished: the initial, the pre-buckling (the effect of the load on the initial shape is accounted not to overestimate the critical load) and the post-buckling state. Figure 2 shows the centroidal axis of the arch in the initial configuration (continuous line) and in the pre-buckling equilibrium state (dashed line) assuming symmetric support and loading conditions. Using a generalized approach, at this point, the arch is rotationally restrained at the ends with torsional springs whose spring constants are \( k_{\gamma} \) and the loading consists of the distributed forces \( f = f_n e_n + f_t e_t \) and the concentrated force \( P_{\xi}(\varphi = 0) \).

Using the principle of virtual work, it is found that the pre-buckling equilibrium is governed by equations (9)

\[
\delta \varepsilon_m = \text{constant},
\]

which are comparable to the equations published in [4]. The post-buckling equilibrium is given by [9]

\[
W_{ob}^{(4)} + (2 + \chi^2 - 1)W_{ob}^{(2)} + \chi^2 W_{ob} = \chi^2 - 1, \quad W_{ob} = w_o / \rho_o, \quad \chi^2 = 1 - m_{en}
\]

or equivalently, in terms of the kinematical quantities this set simplifies to

\[
W_{ob}^{(4)} + (2 + \chi^2 - 1)W_{ob}^{(2)} + \chi^2 W_{ob} = m_{en} \left[ 1 - W_{ob}^{(2)} - W_{ob} \right], \quad W_{ob} = w_o / \rho_o.
\]

4. SOLUTION FOR THE PRE-BUCKLING STATE

Because all the geometry, the loading and the support conditions are symmetric to \( \varphi = 0 \), only a half-arch is modelled – see Figure 3. The general solution satisfying equilibrium equation (9) is sought on the right half of the arch in the form

\[
W_o = \frac{x^2 - 1}{x^2} + A_1 \cos \varphi + A_2 \sin \varphi - \frac{A_3}{x^2} \cos \chi \varphi - \frac{A_4}{x^2} \sin \chi \varphi, \quad A_i \in \mathbb{R}.
\]

The integration constants \( A_i \) can be determined by utilizing the boundary conditions gathered in Table 1. At the right support the displacement and the bending moment are zero. At the crown point the rotation is zero and there is a jump in the shear force distribution with magnitude \( 2 / P \). Altogether, there are four unknowns and four equations in a linear system. Closed-form solutions are possible. With the normal displacement in hand, the rotation can also be calculated recalling Eq. (1). Since the axial strain is constant on the centroidal axis – see Eq. (8) – one can write

\[
\varepsilon_m = \frac{1}{2} \int_0^\varphi \varepsilon_m(\varphi) d\varphi = I_1 + I_2 P + I_3 P^2
\]

where \( P = (-P_o \rho_o \varphi) / (2I_{en}) \) is a dimensionless load. Constants \( I_1, I_2, I_3 \) can be expressed in closed form.

5. SOLUTIONS FOR THE BUCKLED EQUILIBRIUM STATE

The general solution of equation (12) takes the form

$$W_{ob} = C_1 \cos \phi + C_2 \sin \phi + C_3 \sin(\chi \phi) + C_4 \cos(\chi \phi) - \frac{m e_{mb}}{2 \chi^2} \left( \frac{2 + A_3 \sin(\chi \phi) - A_4 \cos(\chi \phi)}{\chi} \right)$$

(15)

while, if the increment $e_{mb}$ is zero, it simplifies to

$$W_{ob}(\phi) = D_1 \cos \phi + D_2 \sin \phi + D_3 \sin \chi \phi + D_4 \cos \chi \phi; \quad C_1, D_j \in \mathbb{R}.$$  

(16)

After buckling, every physical quantity is continuous through the interval $\phi \in [-\vartheta, \vartheta]$ because there is no increment in the loading. Possibly, there is symmetric (or limit point) and antisymmetric (or bifurcation) buckling. If the buckled arch shape is [antisymmetric] (symmetric) then $e_{mb} = 0$ ($e_{mb} \neq 0$). These possibilities are shown on the [left] (right) side in Figure 4.

The continuous line represents the centroidal axis of the arch in the initial configuration, the dashed line is the pre-buckling shape while the dotted line is the buckled shape.

Figure 4: Possible pre-buckling and buckled arch shapes

First let us deal with bifurcation buckling. As all fields are continuous, now the whole arch is considered, consequently the displacement and the bending moment are zero at the end supports. After substituting solution (16) into the boundary conditions (BCs) in Table 2, a homogeneous system of linear equations is found for which nontrivial solution exists if the determinant of the coefficient matrix is set to zero:

$$D = (1 - \chi^2)^2 (1 + \chi^2)^2 \sin \vartheta \cos \vartheta \cos \vartheta \sin \vartheta = 0.$$  

(17)

Recalling the relation $\chi^2 = 1 - m e_m$, the lowest physically possible solution is $\chi = \pi / \vartheta$, thus

$$e_{mb, cri} = \frac{1}{m} \left( 1 - \chi^2 \right) = \frac{1}{m} \left( 1 - \left( \frac{\pi}{\vartheta} \right)^2 \right)$$

(18)

is the lowest (critical) strain.

<td>$W_{ob}^{(2)}(\varphi = \vartheta) = 0$</td>
</tr>
</tbody>
</table>

When dealing with limit point buckling, it is again easier to consider only the right half of the arch. The boundary conditions are presented in Table 3. Upon substitution of solution (15) into the boundary conditions, an inhomogeneous system of equations is found which can be solved in a closed form. With $W_{ob}$ in hand, the rotation increment is $\psi_{onb} = -W_{ob}(1)$, thus, the constant strain increment is

$$e_{mb} = \frac{1}{2 \vartheta} \int_{-\vartheta}^{\vartheta} \left( U_{ob}(\phi) + W_{ob} + \psi_{onb} \psi_{onb} \right) d\phi.$$  

(19)

Observe that $\psi_{on} = -W_{ob}(1)$ is an odd function of $\phi$, consequently if $W_{ob}$ is an odd function of $\phi$ then the above integral indeed vanishes for bifurcation buckling: $e_{mb} = 0$. Otherwise – practically if $W_{ob}$ is an even function in $\phi - e_{mb}$ is a nonzero constant.

</tr>
</tbody>
</table>

Substituting now all the previously determined kinematical quantities into Eq. (19), then performing the integration and simplifying by the constant increment $e_{mb}$, it is found that

$$1 = J_1 + J_2 \mathbf{P} + J_3 \mathbf{P}^2, \quad J_1 \in \mathbb{R}.$$  

(20)
Here each of the constants $J_i$ can be expressed in a closed form [9].

To find the critical load for bifurcation buckling, the critical strain (18) should be substituted to (14). For limit point buckling, nonlinear equations (14) and (20) have to be solved simultaneously for the two unknowns: critical strain and critical load.

6. THE EFFECT OF MATERIAL COMPOSITION ON THE BUCKLING LOAD

It is now investigated how heterogeneity can affect the buckling load of bi-layered arches with rectangular cross-section, given that only the material composition changes -- the overall geometry remains unchanged. As can be seen from Figure 5, the upper layer has Young's modulus $E_1$ and height $b_1$. The height is a parameter: $b_1 \in [0, b]$. When $b_1 = 0$, the arch is homogeneous with Young's modulus $E_2$. In this case, the heterogeneity parameter is always noted by $m_{\text{hom}}$ and the radius of the $E$-weighted centroidal axis is $\rho_{\text{hom}}$. If $b_1 = b$, the homogeneous cross-section has Young's modulus $E_1$. For any other (and obviously heterogeneous) distributions, the notations $m_{\text{het}}$ and $\rho_{\text{het}}$ are used.

Recalling (4), it is intended to find how the ratio

$$\frac{m_{\text{het}}}{m_{\text{hom}}(b_1 = 0)} = \frac{A_2 E_2}{A E_1} \left( \frac{\rho_{\text{het}}}{\rho_{\text{hom}}} \right)^2$$

is related to the material distribution. It turns out that this fraction is a function of the quotients $\rho_{\text{hom}} / b$, $b_1 / b$ and $E_2 / E_1$ for this simple rectangular cross-section. The first, and otherwise dominant term on the right side of the former expression depends only on the ratios $E_2 / E_1$ and $b_1 / b$ -- see the definitions (3)-(4). Some solutions are plotted on Figure 6. On the account of heterogeneity, up to a 55% difference can be experienced when $E_2 / E_1 = 5$. It is also clear that when $b / b_1 = 0.5$, the related curves intersect each other and the maxima of these are also the same. It means that the plotted ratio is obviously independent of whether the upper or the lower layer has greater Young's modulus. The quotient $E_2 / E_1$ only affects at what rate of $b / b_1$ the maximum is reached.

The second term in (21) further depends on the ratio $\rho_{\text{hom}} / b$. For the values 10, 50 and 100, the results are plotted in Figure 7. It can be seen that this term has a much less considerable effect -- at most ±4%, when $\rho_{\text{hom}} / b = 10$. For the other two selected ratios it is always less than 1%. So for most geometries and material distributions the ratio $(\rho_{\text{het}} / \rho_{\text{hom}})^2$ can be considered to be 1 with a good accuracy.

To sum up, the ratio $m_{\text{het}} / m_{\text{hom}}$ is always the product of the previous two matching figures. This quotient for $\rho_{\text{hom}} / b = 10$ is plotted in Figure 8. The maximum value is a considerable 1.589.
Figure 7: Variation of some typical parameters

Figure 8: Possible values for parameter $m$ for various distributions

Figure 9: Change in the lowest buckling load due to various parameters
Let us see now tackle some numerical examples. A circular arch with $E_J / E_1 = 4$ is chosen. The following $m_{hom}$ values are selected: $\{ 1.2 \cdot 10^3; 1.08 \cdot 10^4; 1.0008 \cdot 10^5; 10^6 \}$. It is intended to find how heterogeneity affects the critical load through the variation of the parameter $m$. Investigations are carried out until the maxima of the parameter $m_{het}$ is reached, while gradually increasing the ratio $b_1 / b$ -- see the preceding figures. All the results are shown graphically in Figure 9. For every selected included angle only the dominant buckling mode (either bifurcation or limit-point) is evaluated. When the buckled arch shape is symmetric, the corresponding curve is dashed. When it is antisymmetric (it is the more general for pinned supports), then the curve is continuous.

7. CONCLUSIONS

Overall, it can concluded that heterogeneity has a really considerable effect on the buckling load, independently of the magnitude of the selected $m$ parameter values. This can be up to 50% for antisymmetric case and 41% for symmetric buckling. It is also a conclusion that, the semi-vertex angle $\vartheta$ does not really have an impact on the plotted ratios: the related curves usually coincide in the majority of the interval. On Figure 9, it can as well be observed that increasing the value of $m_{hom}$ results a slight increase in the maxima of the ratio $m_{het} / m_{hom}$ measured along the abscissa.
