INDUSTRIAL AND LABORATORY EXPERIMENTS REGARDING THE DEPHOSPHORIZATION POSSIBILITIES OF HIGHLY ALLIED STEEL WITH MANGANESE

¹: DEPARTMENT OF ENGINEERING & MANAGEMENT, FACULTY OF ENGINEERING HUNEDOARA, UNIVERSITY POLITEHNICA TIMISOARA, REVOLUTIEI 5, 331128, HUNEDOARA, ROMANIA

ABSTRACT: Using the method of austenitic manganese steel waste remelting, we get inevitable, phosphorus contents that exceed the admissible limits. The phosphorus increases the hardness and tensile strength of steel and it seriously affects the ductility and resistance to shock or impact. The practical application of dephosphorization is discussed in the paper. Experiments on the dephosphorization of highly allied manganese steel containing high phosphorous was made in laboratory conditions and the experimental results showed that the content of phosphorous in the steel can be lowered quickly and considerably. The industrial conditions allowed us to obtain similar results with those obtained in the laboratory. The only difference between the two experiments is the dephosphorization level, witch was higher in the laboratory compared to the level obtain on an industrial scale, even if the experiments were done in similar conditions.

KEYWORDS: manganese austenitic steel, dephosphorization, slag, experimentations

INTRODUCTION

Manganese steel (or Hadfield steel) is made by alloying steel, containing 0.8 to 1.25% carbon, with 11 to 15% manganese (an average of around 13% manganese). Many variations of the original austenitic manganese steel have been proposed, but only a few have been adopted as significant improvements. These usually involve variations of carbon and manganese, with or without additional alloys such as chromium, nickel, molybdenum, vanadium, titanium, and bismuth. The mechanical properties of austenitic manganese steel vary with both carbon and manganese content. As carbon is increased it becomes increasingly difficult to retain all of the carbon in solid solution, which may account for reductions in tensile strength and ductility.

Manganese steel is unique non-magnetic steel with extreme anti-wear properties. Also, manganese steel was unique in that it combined high toughness and ductility with high work-hardening capacity and, usually, good resistance to wear. [1-4, 11-12]

Manganese steel is known for its high impact strength and resistance to abrasion. Under shock and during conditions of impact it nearly triples its initial surface hardness and acquires a high polish, without any increase in brittleness which is usually associated with hardness.

It is known the fact that the manganese steel hardness, after the thermal treatment, is situated between 180... 220 HB, but, under the influence of the vibratory load and the high specific pressures, at the surface it is formed a significant number of slip planes and therefore, a consolidation and an increase of secondary hardness. This allows manganese steel to retain its toughness. These features, combined with the high tensile strength, make it an ideal material for heavy impact and abrasive service. Manganese steel performs best in extreme impact applications. [1-3]

Manganese steel has been used in the mining industry, cement mixers, rock crushers, railroad frogs, crawler treads for tractors and other high impact and abrasive environments. Other applications include fragmentizer hammers and grates for automobile recycling and military applications. Giving the destination of these steel, it is very important that the phosphorus content does not exceed the admissible limits (max. 0.11%). [1-3, 5-16, 20]

The phosphorus results in steel from the metallic charges witch can be between 45... 98% recycled waste of manganese steel. Another source to introduce the phosphorus in the metallic bath is the ferro-manganese. The phosphorus, in the manganese steel, can be found as solid solution inside the austenitic granule. When the phosphorus content increases over 0.12%, the free complex phosphide fixes at the austenitic granule margins, witch causes fragility both at low and at high temperatures. [1-4, 6-7, 11-12]

Using the method of austenitic manganese steel waste remelting, we get inevitable, phosphorus contents that exceed the admissible limits. The phosphorus increases the hardness and tensile strength of steel and it seriously affects the ductility and resistance to shock or impact. For this reason, the functioning durability of the manganese steel cast pieces highly decreases and, in the same time, it increases the cull quantity, because of the defects like heat crack and cold crack.

Figure 1. Heat cracks ($P = 0.139\%$), appeared during at the thermal treatment

Figure 2. Heat cracks ($P = 0.134\%$), appeared during at the thermal treatment

Figure 3. Cold cracks, appeared at gagging ($P = 0.136\%$)

Figure 4. Cold cracks, appeared at gagging ($P = 0.139\%$)

The defects in the manganese steel cast pieces, with accent on the defects caused by the increased content of phosphorus, were analyzed in the foundry. In this way, the heat cracks - caused by the high phosphorus content (Figure 1... 2), the cold cracks (Figure 3... 4) and the structural defects in the cast pieces from highly allied steel with manganese appeared (Figure 5... 10). [1-3, 17-19]

LABORATORY EXPERIMENTS AND RESULTS

In the Steel Metallurgy Laboratory, from the Faculty of Engineering - Hunedoara, a series of three tests were made, with the purpose of manganese steel dephosphorization.

The samples, weighing 1 kg, were obtain from cast charges that had a high phosphorus content ($P_{max}=0.11\%$, according to the Romanian standards, Table 1).

With the first sample, we tried a dephosphorization with the slag elimination at melting. In the charge were introduced the following materials:

- 1.8% iron ore (pellet),
- 1.5% lime,
- 1.0% calcium-fluorite.

with means a total of 4.3% addition. After melting, the entire slag was removed, and the liquid steel was cast in the chill mould. The chemical composition of the first sample is presented in Table 2.

With the second sample, the quantity of addition on the charge was increased, as follows:

- 3.0% CaO,
- 1.0% CaF₂,
- 2.0% ACC scrap (autoclaved cellular concrete),
- 2.0 % iron ore (pellet).

with means a total of 8.0% addition. After melting, the slag was removed, and the steel was cast in the chill mould. The chemical composition of the second sample is presented in the same Table 2.

With the third sample, a melting with two slags was attempted. In the charge were introduced the following addition materials:

- 3.0% CaO,
- 3.0% ACC scrap (autoclaved cellular concrete),
- 2.0 % iron ore (pellet).

with means a total of 8% addition. After melting, the slag was removed and we introduced the following additions, in order to form the new slag:

- 2.0% CaO,
- 0.6% CaF₂,
- 0.4% ACC scrap (autoclaved cellular concrete),
- 1.5% FeSi,
- 0.5% Al.

This slag was not removed this time, and the chemical composition of the sample cast in the chill mould is presented in Table 2.

We mention that the casting temperature couldn't be measured in either of the charges.

INDUSTRIAL EXPERIMENTATIONS AND RESULTS

At an industrial scale, with the same purpose as the laboratory experimentations, a dephosphorization in the 3 tone capacity electrical furnace with basic lining has been attempted.

The chemical composition of the charge has been between the limits prescribed by the standards, except the phosphorus. The metallic charge was formed by:

- 70% recycled waste (riser) of manganese steel, with high content of phosphorus, between 0.125... 0.144%, and
- 30% acquired manganese steel waste.

We have been experimented the dephosphorization on three charges. With the first charge, on the load (approximately 3 tones), the following additions have been made:

- 40 kg CaF₂,
- 60 kg iron ore (pellet),
- 80 kg lime.

After melting, the composition of the metallic bath is presented in Table 3.

In this phase, more additions were made on the metallic bath (consisting in 40 kg lime, 30 kg CaF₂ and 15 kg FeSi), after with the correction with FeMn was made, for maintaining the manganese content in the imposed limits.

With the second and third charge, we increased the addition quantities, as follows:

- 45 kg CaF₂,
- 60 kg iron ore (pellet),
- 90 kg lime.

After melting, the chemical compositions of the two charges are presented in Table 3. We mention that the melting slag has not been removed in either of the charges.

CONCLUSIONS

After the laboratory and industrial experimentations, we can draw the following conclusions:

- analyzing the industrial data, one can notice that a manganese steel dephosphorization is possible;
- although the content of manganese is decreasing, at an advanced dephosphorization, the dephosphorated cast iron pieces present a superior resistance to wear compared to cast iron pieces

Table 1. Chemical composition of the samples

Samples no.	% C	% Mn	% Si	% P
1	1.40	13.24	0.83	0.129
2	1.34	13.46	0.76	0.126
3	1.39	13.59	0.33	0.134

Table 2. Chemical composition, after laboratory experiments

Samples no.	% Mn	% Si	% P
1	7.27	0.27	0.034
2	5.74	0.17	0.031
3	8.72	0.31	0.077

Table 3. Chemical composition of the charges, after the industrial experiments

Charges no.	% Mn	% Si	% P
1	8.11	0.19	0.086
2	8.79	0.24	0.091
3	8.94	0.22	0.093

through the remelting without dephosphorization method. In the same time, the quantity of waste is considerable reduced, because of the mentioned defects;

- based on the laboratory experimentations (melting in the graphite crucible furnace), one can observe the possibility to perform the dephosphorization for highly allied steel with manganese;
- if the casting temperatures could have been measured, we consider that the results would have been even more conclusive.

Using the manganese steel waste remelting method, we can inevitable obtain phosphorus quantities that exceed the maximum admissible limit. This is the reason that the functioning durability of the manganese steel casts is decreasing, but, in the same time the waste quantity is increasing considerably, caused by the defects like heat creaks and cold creaks.

The industrial conditions allowed us to obtain similar results with those obtained in the laboratory. The only difference between the two experiments is the dephosphorization level, witch was higher in the laboratory compared to the level obtain on an industrial scale, even if the experiments were done in similar conditions. The motives for witch those differences appeared are:

- the casting temperature, in the laboratory experiments, couldn't been controlled;
- the laboratory conditions did not allow a rigorous control over the quantity and the chemical composition of the slag;
- on a industrial scale, recycled waste presented molding sand adhesion.

Analyzing the obtained data, one can notice that an industrial scale manganese steel dephosphorization is possible.
