# MATHEMATICAL MODELING AND NUMERICAL SIMULATION OF THE DRYING PROCESS OF SEEDS IN A PILOT PLANT

<sup>1.</sup> University of Agricultural Sciences and Veterinary Medicine Iași, ROMANIA

<sup>2.</sup> National Institute of Research-Development for Machines and Installations Designed to Agriculture and Food Industry (INMA) Bucharest, ROMANIA

**Abstract:** The artificial drying of grain seeds is widespread to ensure that they are preserved, as reducing the water content allows products to be stored for long periods of time without the need for complex storage facilities. The proposed drying installation is a low-capacity pilot one, which can change and monitor in real time a series of important parameters of the drying process. By means of the CFD simulation was optimized the construction of the cylindrical box and of the deflectors. This leads to reaching a uniform drying and to reducing the energy consumptions. **Keywords:** mathematical modeling, numerical simulation, seed drying

## 1. INTRODUCTION

The experimental laboratory investigations of cereal seed drying precede the CFD simulation process, because the simulation involves the use of physical parameters (porosity, volume mass, specific heat, conductivity) for both the product and the air used as drying agent.

By CFD simulation of the cereal seed drying process, it is possible to graphically visualize the evolution of temperature and humidity fields at any point in the product layer. Calibration of the simulation is performed by comparison with the experimentally obtained data, measured in the median area of each product layer.

The degree of precision of the mathematical model, obtained by CFD simulation, is given by the differences in temperature and humidity of grain seeds determined under laboratory conditions. Also, an important weight in these differences is also the simplifying assumptions on which the mathematical model of convective drying was built, considering that this process is complex by the large number of physical parameters, as dependent variables, which vary simultaneously over short time.

The concept of a model has many meanings that can refer to a machine, a concept, an equation, a person, etc. In the most general sense, the model is a material or spiritual construction which, depending on the purpose pursued, has a similarity or similar behaviour to the patterned object. The model is a representation of reality, used to analyse the behaviour of the original under different conditions. The model is, in most cases, a simplification of the original, keeping only the essential, significant elements.

There must be an analogy between the original or model object and model. This analogy may be structural or functional. Structural or isomorphic analogy is characterized in that the elements of the original are found in the model. The structure and functionality of the prototype and model are the same. If geometry is preserved, the pattern and the prototype are geometrically similar.

Functional analogy corresponds to simplified models that reproduce only input-output functions from the prototype. For engineering and machine design in the agro-food industry, two types of models are important: mathematical and physical scale.

The use of the Computational Fluid Dynamics technology has made it possible to design and simulate a drying baffled unit for agricultural seed, to achieve uniform seed temperature distribution and to reduce the energy demand.

*Franks* believes that mathematical models are based on three rules: for physical processes, there must be a number of independent equations equal to the number of unknown sizes; from any equation, the solution leads to the value of an unknown; equations are systematized so that each one obtains one of the most significant quantities (Franks, 1961).

Many mathematical models have been developed to simulate the heat and the moisture transfer in the aerated bulk stored grains. A lot of them were obtained at low temperatures and low seed humidity.

*Iguaz et al.* (2004) developed a model for the storage of rough rice during periods with aeration. *Andra* (2001) and *Devilla* (2002) simulated the temperature changes in a wheat storage bin, but, without moisture changes.

*Chang et al.* (1993) and *Sinicio et al.* (1997) also developed a rigorous model to predict the temperature and the moisture content of wheat seeds during storage with aeration.

The aim of this paper is to propose the mathematical model of mass and heat transfer and to simulate the air flow in a cylindrical drying unit with deflectors, using the FLUENT software.

### 2. MATERIAL AND METHOD

CFD analyses can provide complex information on the drying phenomenon that cannot be obtained under experimental conditions. Table 1 presents the capability and limits of the experiment and the CFD numerical simulation by comparative analysis.

Table 1. Comparative analysis between experiment and simulation				
Elements	Experiment	CFD Numerical Simulation

Sources of errors	measurements errors	modeling meshing implementation		

The mathematical model of the convective drying process is based on fluid dynamics, mass balance and energy dynamics theory.

The equations of the mathematical model of the air flow are: the differential equation of continuity, Navier–Stockes equations, mass transfer equation, heat transfer equation and moment transfer equation.

The system of the equations described above is the general mathematical model. This system is solved by numerical procedures, using solving algorithms. Numerical solving by CFD simulation of the equation system in the mathematical model is accomplished by the iterative method using the Gauss-Seidel model. The iterative method of solving the equation system is performed by successive iterations, so based on the previous solutions each iteration calculates a new solution.

The iterative Gauss-Seidel method aims to increase the convergence speed and reduce the memory needed to store the solution in one memory space, not two.

CFD simulation, based on the proposed mathematical model, involves following steps:

- # numerical meshing of the calculation area by the finite volume method (centered difference approximation) in the pre-processing stage;
- # imposing boundary conditions to obtain a determined system of equations, which is done in the pre-processing stage for geometry and in the processing stage for parameters of speed, temperature, humidity;
- # solving the system of equations in each domain node by the interactive method until obtaining the convergence in the processing stage;
- # graphical representation of the solutions obtained at each node in the studied field, for parameters of speed, temperature, humidity and current lines, in the post-processing stage.

During the pre-processing stage are presented the numerical meshing techniques and the limit conditions for obtaining a determined system of equations.

Approximation by meshing is a fundamental concept based on several numerical methods such as finite difference method, finite volume method, finite element method and spectral method.

The numerical discretization of the computation domain in this simulation is done by the finite volume method (centric approximation). Control volume discretization applies to a three-dimensional domain divided into a finite number of adjacent volumes of parallelepipedal shape chosen to contain a single node of the network represented by the coordinates i, j, k and side faces intersecting the lines of the network in points located halfway between two neighbouring nodes (figure 1).

At the basis of this method are the solutions for the integration of an equation on each volume, by choosing a certain distribution law of u(u may be a function of temperature, humidity, displacement of a fluid or product) so that it can be evaluated integrally. The meshed form of the equation contains the function values for a group of nodes of the network, adjacent to the central node.

The areas of separation between the adjacent control volumes are in this case discontinuous surfaces. The values of the function u on these surfaces are considered equal to the arithmetic mean of the values corresponding to the volumes placed on one side and the other, being represented by the relations:

$$u_{i+\frac{1}{2},j,k} = \frac{u_{i+1,j,k} + u_{i,j,k}}{2}; u_{i-\frac{1}{2},j,k} = \frac{u_{i,j,k} + u_{i-1,j,k}}{2}$$
(1)

$$u_{i,j+\frac{1}{2},k} = \frac{u_{i,j+1,k} + u_{i,j,k}}{2} ; u_{i,j,-\frac{1}{2},k} = \frac{u_{i,j,k} + u_{i,j-1,k}}{2}$$
(2)

$$u_{i,j,k+\frac{1}{2}} = \frac{u_{i,j,k+1} + u_{i,j,k}}{2} ; u_{i,j,k-\frac{1}{2}} = \frac{u_{i,j,k} + u_{i,j,k-1}}{2}$$
(3)

where: i, j, k as the index represents the natural number.

By integrating the partial derivative equations on the finite control volume V (V= $\Delta x \cdot \Delta y \cdot \Delta z$ ), the first and second order integrals appear, which will take a discretised form respecting the values of the function in the neighbouring volumes. The discretized form on the three directions will be:

$$\int_{\Delta V} \left(\frac{\partial u}{\partial x}\right) dx dy dz = \left(\frac{u_{i+1,j,k} - u_{i-1,j,k}}{2\Delta x}\right) \Delta V \tag{4}$$

$$\int_{\Delta V} \left( \frac{\partial u}{\partial y} \right) dx dy dz = \left( \frac{u_{i,j+1,k} - u_{i,j-1,k}}{2\Delta y} \right) \Delta V$$
(5)

$$\int_{\Delta V} \left( \frac{\partial u}{\partial z} \right) dx dy dz = \left( \frac{u_{i,j,k+1} - u_{i,j,k-1}}{2\Delta z} \right) \Delta V$$
(6)

where: V represents the volume.

The expressions of the integrals of the mixed derivatives can be obtained using the integration of second-order mixed derivatives:

$$\int_{\Delta V} \left( \frac{\partial^2 u}{\partial x \partial y} \right) dx dy dz = \frac{u_{i+1,j+1,k} - u_{i+1,j-1,k} + u_{i-1,j-1,k} - u_{i-1,j+1,k}}{4\Delta x \cdot \Delta y}$$
(7)

Finite volume discretization involves an analysis of the working range that is volumetric represented by the cylindrical unit. It has the form of a cylinder that has three slots where the cereal seeds are introduced for drying. The hot air enters this cylindrical box through the central region, being guided by a cylindrical tubing that connects to the dryer.

The geometry of the three-layer cylindrical unit and the introduction of the drying agent is shown in figure 2, and the mesh geometry is shown in figure 3.

Figure 3 - Cylindrical box meshing

The cylindrical unit geometry is hybridized. The displacement of the cylindrical introduction of the drying agent is structured, and in the region of the three slots where the seeds are introduced, the meshing is unstructured. The air inlet and outlet area in the free volume and the four vertical surfaces define the free volume and are shown in table 2.

Table 2. Cylindrical	unit imposed	l outline conditions

Entry	Speed
Exit	Pressure
Surfaces	Wall
Volume	Fluid

At the discretization of the pressure and other conservation equations, the upwind mesh scheme (the value of the velocity u is transported to the edge of the volume element relative to the local speed direction) of the first order (Ansys-Fluent-User Guide, 2012). A linear (first order) scheme was used to simulate the pressure equation in order to maintain the stability of the final

solution. The quadratic scheme is more sensitive to pressure deformations, resulting in an instability of the calculation, the solution for the multiphase flow (air plus humidity) and the density (of nodes) imposed by the

meshing. All the simulations were unstated. The flow regime for simulation is tested to obtain a convergent equilibrium state in the evolution of residues (figure 4).

Following the mathematical modeling of the drying process, CFD simulations were made in two variants for the three-layer cylindrical unit with corn seeds from the DKC 4751 hybrid.

#### 3. RESULTS

The field of the current lines obtained in the threelayered cylindrical unit has a laminar flow of the drying agent at the unit entrance, and in the region of the baffles, one can see a uniform distribution of the hot air over the entire surface of the corn seeds to be dried. In the simulation version I, with a thermal velocity of 2 m/s and its inlet temperature

Figure 4 - Developments in processing residues for non-steady state

of 313 K (40 °C), a speed increase of up to almost 8 m/s is observed in the deflector region as a result of the reduction of the section and afterwards it reaches uniformly again the value of 2 m/s on the surface of the first seed bed. Passing the three layers of corn seeds, the speed of the current lines drops to 0.3 m/s at the exit of the last layer (figure 5a). The surface temperature of the first seed coat is 313 K (40 °C) with a uniform distribution of current lines, and in the seed layers the temperature decreases, yielding heat for drying and lowering to the last layer up to 300 K (27 °C), figure 5b.

In the CFD simulation variant II at an air velocity of 2 m/s and its inlet temperature of 343 K (70 °C), the same speed increase in the deflector region is observed as a result of the section reduction, which will be uniformly reached again at 2 m/s on the surface of the first grain seed bed. Passing the three layers of corn seed, the current line speed drops to 0.3 m/s at the exit of the last layer. The distribution of air velocity in the three-layer cylindrical box is preserved as in variant I, with very small variations, as the geometry remains unchanged (figure 6a).

# Figure 5 - The current lines field inside the cylindrical box with baffles and three layers for the first version (temperature of 313 K = 40°C): a – velocity (m/s); b – temperature (K).

The temperature at the surface of the first seed bed is 343 K (70 °C) with a uniform distribution of the current lines, and in the seed layers, the temperature decreases giving off their heat for drying and lowering to the last layer to 311 K (38 °C). As shown in fig. 5 and fig. 6, regardless of the working regime of the drying unit, the same uniformity of the current lines is maintained over the whole surface of the first layer of seeds. In the design phase of the three-layer cylindrical unit, the distance between the baffles and sections was optimized by repeated CFD simulations to achieve this uniformity of spreading of the drying agent at the layers of corn seeds. In order to obtain the seed temperature and humidity parameters CFD simulation was performed at two different temperatures of the hot air.

### 4. CONCLUSIONS

After the drying process mathematical modeling, CFD simulations have been made in two variants for the cylindrical box with three corn seeds layers.

The results regarding the distribution of the corn seed humidity, in the three layers of the cylindrical box in the second variant, had medium values that varied from the first to the last layer as it follows: the medium value reached was 11,5% in the first layer, 17% in the second, and 21% in the third one.

By means of these CFD simulations calibrated with the experiment, one can make a sufficiently exact model, so that it could be used for other types of seeds too. The main condition is that the entry data introduced in the simulation and obtained experimentally should be as exact as possible. By means of the CFD simulation one can optimize the working process in the cereal seed drying.

Also, by means of the CFD simulation was optimized the construction of the cylindrical box and of the deflectors so that one could obtain a uniform distribution of the air currents and of the temperature fields in the three cereal seed layers. This leads to reaching a uniform drying and to reducing the energy demand.
